Abstract

1 Introduction

Simultaneously imaging large populations of neurons using calcium sensors is becoming increasingly popular [1, 2, 3, 4], especially as the signal-to-noise-ratio (SNR) of genetic sensors continues to improve [5, 6, 7]. While this technology facilitates acquiring data from an unprecedented number of neurons simultaneously, it is not yet a panacea: there is a trade-off between the quantity of neurons, and the quality of data. While one can now acquire data from ~ 100 neurons within a single experimental session, the data for each neuron is relatively poor. In comparison with extracellular electrophysiology, the data from calcium imaging has reduced (i) SNR and (ii) temporal resolution. Thus, relatively few studies have been able to use this approach to date to ask *quantitative* questions about the relationship between spike trains, and, for example, sensory stimuli [8, 9, 10, 11, 12, 13, 14].

A number of groups have proposed spike inference algorithms to facilitate using calcium imaging to ask quantitative questions about spike timing. Finding the most likely spike train, given a calcium movie, is computationally intractable because we have to perform a search over all possible spike trains, and the number of possible spike trains scales exponentially with the number of image frames, T (more specifically, assuming only a single spike can occur per frame, we have 2^T possible spike trains). To circumvent this problem, various groups have developed distinct strategies. For instance, Greenberg et al. [15] reduced the search space by establishing heuristics to preprocess the data, and effectively exclude many image frames from the search space. In our previous work [16], we developed a sequential Monte Carlo method to efficiently sample spike trains given the fluorescence data, which is guaranteed to perform optimally given our model, which incorporates saturation, refractoriness, and stimulus dependent effects (this approach has the added advantage of providing a measure of uncertainty as well). Unfortunately, both these approaches are relatively slow, as they still require searches over large spaces. Holekamp et al. [17] took a very different strategy, by performing the optimal linear deconvolution (i.e., the Wiener filter) on the fluorescence data. This approach may be thought of as finding the *maximum a posteriori* (MAP) spike train.

The present work also develops a deconvolution filter, but has several advantages over the Wiener filter. First, we impose a non-negative constraint on the solution. Because we know that spikes are non-negative events, this is a desirable constraint to impose on our inference procedure. In practice, this constraint regularizes the resulting inference [18, 19, 20], by combating against "ringing" overfitting effects. Second, the computational time of our filter scales linearly with T, whereas the Wiener filter typically scales according to $T \log T$. Thus, we have named our approach the FAst Non-negative Deconvolution (FAND) filter. This FAND filter could be applicable in a number of scientific investigations from myriad fields, and is closely related to the problem of non-negative matrix factorization, a problem currently receiving much attention from the machine learning community [21, 18, 19, 22, 23].

The remainder of this paper is organized as follows. In Section 2, we describe our parametric model, and the FAND filter. Section 3 first provides our main result: we can utilize FAND to filter calcium fluorescence data, with better results than the optimal linear filter. We then generalize the FAND filter in a number of directions. First, instead of assuming the data is a 1-dimensional fluorescence time series, we operate on all the pixels within a region-of-interest (ROI), which can significantly improve the SNR of our inference. Second, by embedding our FAND filter into a pseudo-expectation-maximization algorithm, we can learn the parameters of our model without any training data (i.e., without requiring simultaneous imaging and electrophysiology). To demonstrate the utility of this approach, we compare our filter and the Wiener filter's output on in vitro data. Third, when imaging a large population of neurons simultaneously, sometimes segmenting the image to obtain one neuron per ROI is difficult. Therefore, we show how approach can be further generalized to deal with such a scenario. We then apply our filter to a movie of ~ 50 neurons recorded simultaneously in vitro, to indicate that this approach works "out-of-the-box" on segmented data. Fourth, we modify our model to handle data collected in vivo using genetic sensors. Specifically, this means allowing for a slow rise time and poisson observations. Finally, in the discussion, we show how to incorporate non-linear saturation into the FAND filter, and discuss how the output of our FAND filter can be used to initialize our more powerful (but slower) algorithms.

2 Methods

2.1 Model

We start by assuming a very simple generative model, relating the hidden neural activity (spike trains and intracellular calcium concnetrations) and the observations (fluorescence movies). More specifically, we start by assuming we have collected a 1-dimensional fluorescence trace, $\mathbf{F} = (F_1, \dots, F_T)$ from a neuron. At time t, the fluorescence measurement, F_t is a linear-Gaussian function of the intracellular calcium concentration at that time, C_t :

$$F_t = \alpha(C_t + \beta) + \sigma \varepsilon_t, \qquad \varepsilon_t \stackrel{iid}{\sim} \mathcal{N}(0, 1)$$
 (1)

The scale, α , absorbs all experimental variables impacting the scale of the signal, including number of sensors within the cell, photon/ $\Delta[\text{Ca}^{2+}]$ per sensor, amplification of imaging system, etc. Similarly, the offset, β , absorbs baseline calcium concentration of the cell, background fluorescence of the fluorophore, imaging system offset, etc. The standard deviation, σ , results from calcium fluctuations independent of spiking activity, fluorescence fluctuations independent of calcium, and imaging noise. These three parameters therefore correspond to a number of simplifying assumptions, that we will relax in Section 3.

We further assume that the intracellular calcium concentration, C_t , jumps after each spike, and subsequently decays back down to rest with time constant, τ , yielding $\tau(C_t - C_{t-1})/\Delta = -C_{t-1} + n_t$. Rearranging (and rescaling) a bit, we have:

$$C_t = \gamma C_{t-1} + n_t, \qquad n_t \stackrel{iid}{\sim} \text{Poisson}(\lambda \Delta)$$
 (2)

where n_t indicates the number of times the neuron spiked at time t, and $\gamma = 1 - \Delta/\tau$. Note that C_t does not refer to absolute intracellular concentration of calcium but rather, a relative measure. The assumed linearity of our model precludes the possibility of determining calcium in absolute terms (but see Section 4.1 for a modified model). Figure 1 depicts a schematic illustration of this model. Note that the model, Eqs. (1) and (2) is a discrete-time state-space model. Importantly, this model differs from the standard models in that we have a non-Gaussian noise term, n_t . Thus, standard tools, such as the Kalman filter-smoother, cannot be applied directly. We therefore develop a novel algorithm to handle problems of this nature, as described below.

 $^{^{1}\}text{This}$ follows from writing (2) as $\tau\frac{C_{t}-C_{t-1}}{\Delta}=-C_{t-1}+n_{t}.$

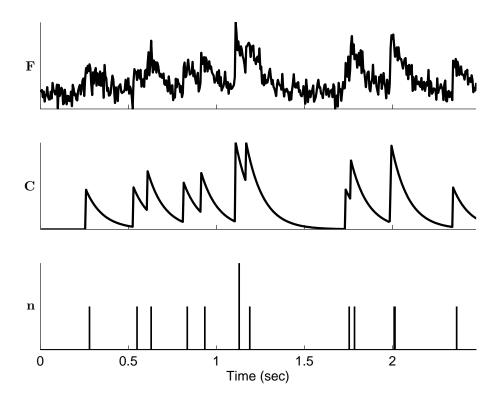

Figure 1: A schematic illustrating our model. The spike train (bottom panel) is convolved with an exponential with time constant τ to obtain the calcium dynamics (middle panel). The fluorescence observations are simply the calcium dynamics, plus zero mean Gaussian noise (with variance σ^2). Parameters: $\Delta=5$ msec, $\alpha=1$ photons/ μ M, $\beta=0$ unitless, $\sigma=0.25$ photons, $\tau=100$ msec, $\lambda=5$ Hz.

2.2 Goal

Given the above model, our goal is to find the maximum *a posteriori* (MAP) spike train, i.e., the most likely spike train, n, given the fluorescence measurements, F. Formally, we have:

$$\boldsymbol{n}_{MAP} = \underset{\boldsymbol{n}_{t} \in \mathbb{N}_{0} \forall t}{\operatorname{argmax}} P[\boldsymbol{n} | \boldsymbol{F}]$$
(3a)

$$= \operatorname*{argmax}_{n_t \in \mathbb{N}_0 \forall t} P[\boldsymbol{F} | \boldsymbol{n}] P[\boldsymbol{n}]$$
(3b)

$$= \underset{n_t \in \mathbb{N}_0 \forall t}{\operatorname{argmax}} \prod_{t=1}^T P[F_t | C_t] P[n_t] = \underset{n_t \in \mathbb{N}_0 \forall t}{\operatorname{argmax}} \sum_{t=1}^T \left(\log P[F_t | C_t] + \log P[n_t] \right)$$
(3c)

where 3a is the definition of the MAP spike train, 3b follows from Bayes' Rule, 3c follows from the state-space nature of our problem, \mathbb{N}_0 is the set of natural numbers (i.e., $\mathbb{N}_0 = \{0, 1, 2, \ldots\}$), T is the number of time steps in the recording, and C_t is implicitly a function of n_t . Plugging Eqs. (1) and (2) into Eq. (3c) yields:

$$\boldsymbol{n}_{MAP} = \underset{n_t \in \mathbb{N}_0 \forall t}{\operatorname{argmin}} \sum_{t=1}^{T} \left(\frac{1}{2\sigma^2} (F_t - \alpha (C_t + \beta))^2 - n_t \log \lambda \Delta + \log n_t! \right), \tag{4}$$

Unfortunately, solving Eq. (4) exactly is computationally intractable, as it requires a nonlinear search over all possible spike trains (and since $n_t \in \mathbb{N}_0$, there are an infinite number of them). We could restrict our search space by imposing

an upper bound, k, on the number of spikes within a frame. However, in that case, the computational complexity scales exponentially with the number of image frames — more specifically, requires $O(k^T)$ time — which for pragmatic reasons is intractable. Thus, we approximate Eq. (4), by modifying Eq. (2), replacing the Poisson distribution with one that yields a log-concave problem. This reduces the algorithmic complexity from requiring a search over $O(k^T)$ possible spike trains, to some kind of gradient ascent solution.

Two distributions naturally arise as possible approximations to a Poisson: (i) exponential, and (ii) Gaussian. As depicted in Figure 2 an exponential distribution (dashed gray line) is an excellent approximation to the Poisson distribution (solid black line), when λ is small (left panel). On the other hand, when λ is large, a Gaussian distribution (dash-dotted gray line) closely approximates a Poisson when λ is large (right panel). Thus, naïvely, it seems as though it may be desirable to use a Gaussian approximation when the neuron is firing with a high firing rate, and approximate the Poisson with an exponential when the neuron is firing sparsely. The Wiener filter is, in fact, the optimal filter given the Gaussian approximation [24] (see [17] for an application of the Wiener filter to this problem). Below, we develop an algorithm to perform inference given the exponential distribution.

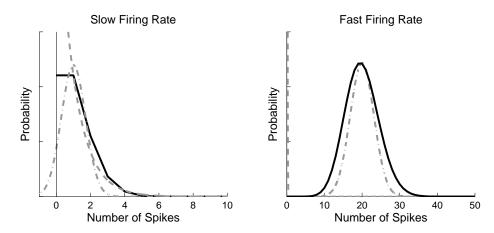

Figure 2: Approximating a Poisson distribution. Left panel: when λ is small (e.g., \approx 1), an exponential distribution (dashed gray line) approximates the Poisson distribution (solid black line) well, but a Gaussian distribution (dash-dotted gray line) does not. Right panel: when λ is large (e.g., \approx 20), the inverse is true.

2.3 Inference

FAst Non-negative Deconvolution (FAND) Filter Our goal here is to develop an algorithm to efficiently approximate \hat{n}_{MAP} . The main contribution of this work demonstrating that we can substitute the Poisson distribution with an exponential distribution, reducing computational complexity from $O(k^T)$ to O(T). Formally, we replace Eq. (2) with:

$$C = \gamma C_{t-1} + n_t, \qquad n_t \stackrel{iid}{\sim} \text{Exponential}(\lambda \Delta)$$
 (5)

where the only difference between Eq. (2) and Eq. (5) is the distribution on n_t . Plugging this change into Eq. (??) yields

$$\boldsymbol{n}_{FAND} = \underset{n_t > 0 \,\forall t}{\operatorname{argmax}} \sum_{t=1}^{T} \left(\frac{1}{2\sigma^2} (F_t - \alpha (C_t + \beta))^2 + n_t \lambda \Delta \right)$$
(6)

where the constraint on n has been relaxed from $n_t \in \mathbb{N}_0$ to $n_t \geq 0$ (since the support of an exponential distribution is the non-negative number line). Note that this is a common approximation technique in the machine learning literature [25], as it is the closest convex relaxation to its non-convex counterpart. While this convex relaxation makes the problem tractable, the "sharp" threshold imposed by the non-negativity constraint prohibits the use of standard gradient ascent techniques [26]. We therefore take an "interior-point" (or "barrier") approach, in which we drop the sharp

threshold, and add a barrier term, which must approach $-\infty$ as n_t approaches zero (e.g., $-\log n_t$) [26]. By iteratively reducing the weight of the barrier term, we are guaranteed to converge to the correct solution [26]. Thus, our goal is to efficiently solve:

$$\widehat{\boldsymbol{n}}_z = \underset{n_t \forall t}{\operatorname{argmin}} \sum_{t=1}^T \left(\frac{1}{2\sigma^2} (F_t - \alpha (C_t + \beta))^2 + n_t \lambda \Delta - z \log(n_t) \right), \tag{7}$$

Since spikes and calcium are related to one another via a simple linear transformation, namely, $n_t = C_t - \gamma C_{t-1}$, we may rewrite Eq. (7) in terms of C:

$$\widehat{C}_{z} = \underset{C_{t} - \gamma C_{t-1} \ge 0 \forall t}{\operatorname{argmin}} \sum_{t=1}^{T} \left(\frac{1}{2\sigma^{2}} (F_{t} - \alpha (C_{t} + \beta))^{2} + (C_{t} - \gamma C_{t-1}) \lambda \Delta - z \log(C_{t} - \gamma C_{-1}) \right). \tag{8}$$

The concavity of Eq. (8) facilitates utilizing any number of techniques guaranteed to find the global optimum. The fact that the argument of Eq. (8) is twice differentiable, suggests that we use the Newton-Raphson technique. Importantly, the state-space nature of this problem yields a particularly efficient approach. Specifically, note that the Hessian is *tridiagonal*, which is clear upon rewriting (8) in matrix notation:

$$\widehat{\boldsymbol{C}}_z = \underset{\boldsymbol{M}\boldsymbol{C} > \boldsymbol{0}}{\operatorname{argmin}} \frac{1}{2\sigma^2} \|\boldsymbol{F} - \alpha(\boldsymbol{C} + \beta)\|^2 + (\boldsymbol{M}\boldsymbol{C})^\mathsf{T} \boldsymbol{\lambda} - z \log(\boldsymbol{M}\boldsymbol{C})^\mathsf{T} \boldsymbol{1}, \tag{9}$$

where $M \in \mathbb{R}^{T \times T}$ is a bidiagonal matrix, $MC \geq 0$ indicates that every element of MC is greater than or equal to zero, $^{\mathsf{T}}$ indicates transpose, $\mathbf{1}$ is a T dimensional column vector, $\mathbf{\lambda} = \lambda \Delta \mathbf{1}^{\mathsf{T}}$, and $\log(\cdot)$ indicates an element-wise logarithm. Note that Eq. (9) follows from writing \mathbf{n} in terms of M and C:

$$MC = \begin{bmatrix} 1 & 0 & 0 & \cdots & \cdots \\ 1 & -\gamma & 0 & \cdots & \cdots \\ 0 & 1 & -\gamma & 0 & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 1 & -\gamma \end{bmatrix} \begin{bmatrix} C_1 \\ C_2 \\ \vdots \\ \vdots \\ C_T \end{bmatrix} = \begin{bmatrix} n_1 \\ n_2 \\ \vdots \\ \vdots \\ n_T \end{bmatrix} = \mathbf{n}$$
(10)

Thus, a little bit of calculus yields our update algorithm for C_z :

$$\hat{\boldsymbol{C}}_z \leftarrow \hat{\boldsymbol{C}}_z + s\boldsymbol{d} \tag{11a}$$

$$Hd = q \tag{11b}$$

$$g = -\frac{\alpha}{\sigma^2} (\mathbf{F} - \alpha (\widehat{\mathbf{C}}_z^{\mathsf{T}} + \beta)) + \mathbf{M}^{\mathsf{T}} \lambda - z \mathbf{M}^{\mathsf{T}} (\mathbf{M} \widehat{\mathbf{C}}_z)^{-1}$$
(11c)

$$\boldsymbol{H} = \frac{\alpha^2}{\sigma^2} \boldsymbol{I} + z \boldsymbol{M}^\mathsf{T} (\boldsymbol{M} \hat{\boldsymbol{C}}_z)^{-2} \boldsymbol{M}$$
 (11d)

where s is the step size, d is the step direction, and g and H are the gradient (first derivative) and Hessian (second derivative) of the argument in Eq. (9) with respect to C, respectively, and the exponents indicate element-wise operations. Note that we use "backtracking linesearches", meaning that for each iteration, we find the maximal s that is (i) between 0 and 1 and (ii) decreases the likelihood.

Typically, implementing Newton-Raphson requires inverting the Hessian, i.e., $d = H^{-1}g$, a computation consuming $O(T^3)$ time. Already, this would be a drastic improvement over the most efficient algorithm assuming Poisson spikes, which require $O(k^T)$ time (where k is the maximum number of spikes per frame). Here, because M is bidiagonal, the Hessian is tridiagonal, the solution may be found in O(T) time via standard banded Gaussian elimination techniques (which can be implemented efficiently in Matlab using $H \setminus g$). In other words, the above approximation and inference algorithm reduces computations from exponential time to linear time. We refer to this fast algorithm for solving (6) the FAst Nonnegative Deconvolution (FAND) filter.

Fast Wiener Filter Instead of replacing the Poisson distribution on spikes with an exponential, we can replace it with a Gaussian:

$$C = \gamma C_{t-1} + n_t, \qquad n_t \stackrel{iid}{\sim} \mathcal{N}(\lambda \Delta, \lambda \Delta)$$
(12)

which, when plugged into Eq. (3c) yields

$$\boldsymbol{n}_{Wiener} = \underset{n_t}{\operatorname{argmax}} \sum_{t=1}^{T} \left(\frac{1}{2\sigma^2} (F_t - \alpha (C_t + \beta))^2 + \frac{1}{2\lambda \Delta} (n_t - \lambda \Delta)^2 \right)$$
(13)

Using the same tridiagonal trick as above, we can solve Eq. (13) using Newton-Raphson once (since we have a quadratic problem here, see Appendix A for details). Because we know only positive spikes are possible, at times we will also consider, [Wiener]₊, which is the Wiener filter half-wave rectified, i.e., all sub-zero values are set to zero.

2.4 Assessment

Let \hat{n} be the inferred spike train, using some algorithm, and n be the true spike train. We compute the following four measures of inference quality (a) correlation coefficient, (b) mean square error, and (c) signal-to-noise ratio:

$$\rho_{\hat{n}} = \frac{\sigma_{n\hat{n}}}{\sigma_{n}\sigma_{\hat{n}}} \tag{14a}$$

$$MSE_{\widehat{n}} = \frac{1}{T} \sum_{t} (n_t - \widehat{n}_t)^2$$
 (14b)

$$SNR_{\widehat{\boldsymbol{n}}} = \frac{\sum_{t|n_t=1} \widehat{n}_t}{\sum_{t|n_t=0} \widehat{n}_t}$$
 (14c)

where $\sigma_{n\widehat{n}}$ is the covariance between n and \widehat{n} and $\sigma_{\widehat{n}}$ is the variance of \widehat{n} , $I\{x\} = 1$ if x is true, and 0 otherwise, and $\mathcal{K} = \{0, 0.1, 0.2, \dots 1\}$. Note that SNR and AUC are only appropriate assuming that there is at most one spike within an image frame.

3 Results

3.1 Main Result

The main result of this paper is that we can approximate n_{MAP} in *linear* time, whereas an exact solution would require exponential time. Fig. 3 shows two examples of running the FAND filter on simulated data. On the left, the data is simulated according to Eqs. (1) and (2), with a low expected firing rate (5 Hz). The FAND filter performs very well (middle left panel): when spikes occured (gray downward facing triangles), the FAND filter's output is relatively high, and in the absence of a spike, the FAND filter's output is relatively low. The height of the "spikes" in n_{FAND} can be thought of as the probability of a spike having occurred. The Wiener filter does not perform as well on this data. Specifically, n_{Wiener} exhibits a "ringing" effect, in which the inference oscillates around zero in the absence of true spikes. This occurs because negative spikes improve the inference, if negative spikes are allowed. By constraining our inference to be non-negative (for the FAND filter), we completely circumvent this problem.

It is unsurprising that the FAND filter significantly outperforms the Wiener filter when spiking is sparse, given that the exponential is a much better approximation to the Poisson in this regime (c.f. Figure 2). However, even in the fast firing rate scenario, where the Gaussian approximation is far more accurate, the FAND filter performs relatively well, as depicted in the right panels of Figure 3. Note however that the computational time for computing the FAND filter scales linearly with T, i.e. is O(T), whereas the naïve implementation of the Wiener filter requires $O(T \log T)$ (but see Appendix ?? for an implementation of the Wiener for that only requires O(T)).

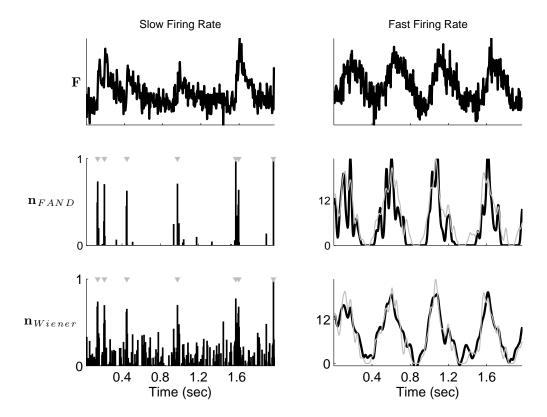

Figure 3: A simulation demonstrating that the FAND filter performs at least as well as the optimal linear (i.e., Wiener) filter. The left panels show that in the slow firing regime, the FAND filter outperforms the Wiener filter in terms of SNR. This "makes sense", given that if a neuron is spiking according to a Poisson distribution with a slow rate, an exponential distribution is a better approximation than a Gaussian distribution, and the FAND filter approximates the spike train distribution with an exponential, versus the Wiener filter's Gaussian. The right panels show that both approximations are sufficient in the fast firing regime. Top left panel: fluorescence time series for a neuron with a slow firing rate. Middle left panel: the FAND filter's inferred spike train. Bottom left panel: Wiener filter's inferred spike train. Note that (i) the Wiener filter does not impose a non-negativity constraint, and (ii) the effective SNR of the Wiener filter in this example is worse than the FAND filter's. Top right panel: same as top left panel, for a neuron with a high firing rate. Middle right panel: the FAND filter's inferred spike train smoothed with a Gaussian kernel for visualization purposes (black line), and the true spike train smoothed with the same Gaussian kernel (gray line). Bottom right panel: same as middle right panel, but with the Wiener filter. Parameters for left panels: same as above. Parameters for right panels: same as above, except: $\sigma = 8$ photons, $\lambda = 500$ Hz.

To quantify the relative quality of these inference algorithms in the sparsely spiking regime, we compute a number of distance measures between n and our inferred \hat{n} : (a) cross correlation, (b) mean square error, and (c) signal-to-noise ratio (see Section 2.4 for details). Figure 4 (top panels) shows how the various algorithms (FAND in blue, Wiener in red, half-wave-rectified Wiener in green, dF/F in turquise) perform according to each of these measures, as a function of the noisiness of the data. Clearly, regardless of the variance of the noise, the FAND filter outperforms all other approaches considered here. On the contrary, in the high firing rate regime, the Wiener filter is optimal, as expected (lower left panels). Note that SNR is only an appropriate measure when there is at most one spike per image frame. Finally, do demonstrate that our algorithms are indeed linear in the number of time steps, we show how computational time scales with T (lower right panel) for each algorithm.

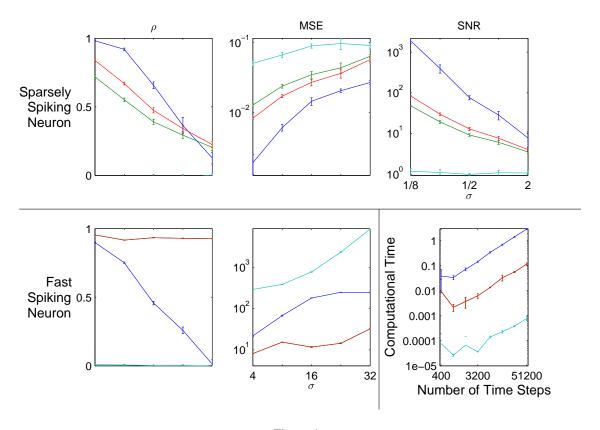

Figure 4:

Finally, often one is interested in understanding the relationship between spike trains and the environment. Therefore, we simulated a neuron whose spiking activity was a function of a 5-dimensional external stimulus. More specifically, we let $\lambda = k^T x$, where k is a 5-dimensional linear kernel, and $x = (x_1, \dots, x_T)$ is the stimulus, and $P(n_t) = \text{Poisson}(\lambda_t \Delta)$. We then computed the maximum likelihood estimate of the linear kernel, $\hat{k} = \hat{n}x^T(xx^T)^{-1}$. Importantly, the simulation was constructed to incorporate both sparse spiking and fast spiking periods, much like sensory neurons have periods of quiescence, followed by stimulus driven bursts. Thus, neither the FAND filter nor the Wiener filter's assumptions are entirely appropriate. Figure 5 shows the results of this simulation. The true kernel, kernel estimated using the true spike times, and kernel estimated using the FAND filter, are nearly overlapping (black, gray, and blue lines, respectively). The kernel estimated using the Wiener filter output, however, is effectively flat (red line). Post-hoc half-wave rectification of the Wiener filter output does not improve its ability to estimate this kernel (green line — completely obscured by the unrectified Wiener filter output). Finally, dF/F does not yield anything useful at all (turquoise line).

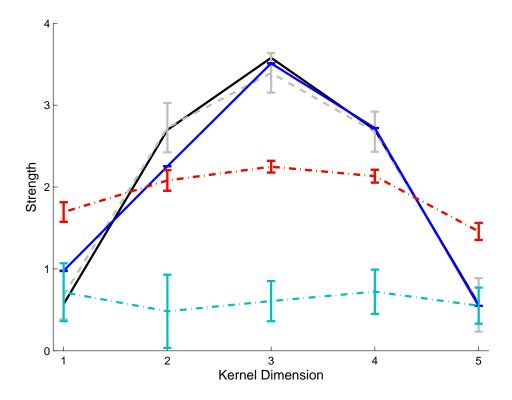

Figure 5: XXX. Parameters: T=800, $\Delta=5$ msec, $\alpha=1,$ $\beta=0,$ $\tau=100$ msec, $x_{i,t}\sim\mathcal{U}(0,0.2),$ $\sigma=1/4.$

3.2 Spatial Filtering

In the previous sections, we implicitly assumed that the raw movie of fluorescence measurements collected by the experimenter had undergone two stages of pre-processing. First, the movie was segmented, to determine regions-of-interest (ROIs). This yields a vector, \vec{F}_t , corresponding to the fluorescence intensity at time t for each of the N_p pixels in the ROI. Second, we projected that vector into a scalar, yielding F_t , the assumed input. In this section, we still assume that somebody has gone through our movies and performed some segmentation, but we do not assume that they have projected the vector \vec{F}_t into a scalar F_t . Formally, we posit a more general model:

$$\vec{F}_t = \vec{\alpha}(C_t + \beta) + \sigma \vec{\varepsilon}_t, \qquad \qquad \vec{\varepsilon}_t \sim \mathcal{N}(\vec{0}, \mathbf{I})$$
 (15)

where $\vec{F_t}$, $\vec{\alpha}$, $\vec{\varepsilon_t}$, and $\vec{0}$ are all column vectors of length N_p , and I is an $N_p \times N_p$ identity matrix. This model follows from the observation that the fluorescence at any individual pixel is composed of a static element, β , and a dynamic element, that we assume is purely due to calcium fluctuations, C_t . Further, we have assumed that the noise is uncorrelated and has the same variance, σ^2 , in each pixel (an assumption that can be relaxed quite easily). Performing inference in this more general model proceeds nearly identical as before,

$$\widehat{\boldsymbol{C}}_{z} = \underset{\boldsymbol{M}\boldsymbol{C} > \mathbf{0}}{\operatorname{argmin}} \frac{1}{2\sigma^{2}} \left\| \vec{\boldsymbol{F}} - \vec{\alpha} (\boldsymbol{C}^{\mathsf{T}} + \beta \mathbf{1}^{\mathsf{T}}) \right\|^{2} + (\boldsymbol{M}\boldsymbol{C})^{\mathsf{T}} \boldsymbol{\lambda} - z \log(\boldsymbol{M}\boldsymbol{C})^{\mathsf{T}} \mathbf{1},$$
(16)

$$g = -\frac{\alpha}{\sigma^2} (F - \alpha (\widehat{\boldsymbol{C}}_z^{\mathsf{T}} + \beta)) + \boldsymbol{M}^{\mathsf{T}} \boldsymbol{\lambda} - z \boldsymbol{M}^{\mathsf{T}} (\boldsymbol{M} \widehat{\boldsymbol{C}}_z)^{-1}$$
(17)

$$H = \frac{\alpha^{\mathsf{T}} \alpha}{\sigma^2} I + z M^{\mathsf{T}} (M \hat{C}_z)^{-2} M$$
(18)

Figure 6 demonstrates the utility of this generalization. The top row shows different depictions of an ROI containing a single neuron, all using the same color scale. On the far left panel is the "true" spatial filter. Importantly, some pixels are *anti-correlated* with others, as indicated by certain pixels being black, and others white. Such a scenario can often arise in both in vitro and in vivo recordings, as the concentration of calcium immediately outside the cell often decreases after a spike, as the calcium ions flow into the cell. Unsurprisingly, the mean frame looks very similar to the true spatial filter, as individual frames are effectively just modulating the magnitude of the spatial filter, and adding noise. Typically, one would simply identify the pixels with high positive values from the mean frame, and average them together. Such an approach yields the 1-dimensional fluorescence projection depicted on the left middle panel, with its associated inferred spike train beneath. Using the true spatial filter to project \vec{F} onto a 1-dimensional fluorescence time series results in the middle right panel, with its associated inferred spike train beneath. It should be clear that using the true spatial filter improves the SNR of the fluorescence signal, and therefore, the inferred spike train accuracy.

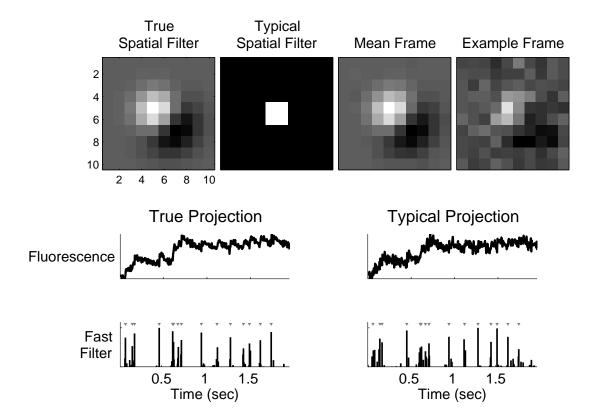

Figure 6: A simulation demonstrating that using a better spatial filter can significantly enhance the effective SNR (see Supplementary Movie 1 for the full movie associated with this simulation). Top: four movie frames. Middle left: projection of the entire movie onto the optimal spatial filter, yielding a 1D fluorescence time series, with a large SNR. Bottom left: FAND filter's inferred spike train using the optimal spatial filter. Middle right: projection of the entire movie onto the "mean" spatial filter, yielding a 1D fluorescence time series with a small SNR. Bottom right: FAND filter's inferred spike train using the mean spatial filter. Parameters different from Fig 1: α is a mixture of two 2D-Gaussians, with mean $\mu_1 = \mu_2 = [0,0]$ and covariance matrices, $\Sigma_i = \sigma_i^2 \mathbf{I}$, with $\sigma_1 = 2$ and $\sigma_2 = 4$ and \mathbf{I} is the identity matrix. $\boldsymbol{\beta} = 1$.

3.3 Learning

In the above, we assumed that the parameters governing our model, $\theta = \{\alpha, \beta, \sigma, \gamma, \lambda\} \in \Theta$, were known. In general, however, these parameters must be estimated from the data. To find the maximum likelihood estimator for the parameters, $\hat{\theta}$, we must integrate over all possible spike trains. Unfortunately, it is not currently known how to perform this integral exactly, and approximating this integral using Monte Carlo methods is relatively time consuming (see [16] for details). Thus, we resort to a more drastic approximation, commonly used in state-space models. For specifically, instead of integrating over all possibly spike trains, we only consider the most likely sequence (ofter referred to as the Viterbi path [27]):

$$\widehat{\boldsymbol{\theta}} = \underset{\boldsymbol{\theta} \in \boldsymbol{\Theta}}{\operatorname{argmax}} \int P[\boldsymbol{F}|\boldsymbol{C}, \boldsymbol{\theta}] P[\boldsymbol{C}|\boldsymbol{\theta}] d\boldsymbol{C} \approx \underset{\boldsymbol{\theta} \in \boldsymbol{\Theta}}{\operatorname{argmax}} P[\boldsymbol{F}|\widehat{\boldsymbol{C}}, \boldsymbol{\theta}] P[\widehat{\boldsymbol{C}}, |\boldsymbol{\theta}]$$
(19)

where \hat{C} is determined using the above described inference algorithm. The approximation in (19) is good whenever the likelihood is very peaky, meaning that most of the mass is around the MAP sequence.²

Due to the state space nature of the above model (Eqs (15) and (2)), the optimization in Eq (19) simplifies significantly. More specifically, we can write the argument from the right-hand-side of Eq (19) as a product of terms that we have defined in our model:

$$P[\boldsymbol{F}|\widehat{\boldsymbol{C}},\boldsymbol{\theta}]P[\widehat{\boldsymbol{C}}|\boldsymbol{\theta}] = \prod_{t=1}^{T} P[F_t|\widehat{C}_t,\boldsymbol{\alpha},\boldsymbol{\beta},\boldsymbol{\sigma}]P[\widehat{C}_t|\widehat{C}_{t-1},\widehat{n}_t,\boldsymbol{\gamma}]P[\widehat{n}_t|\boldsymbol{\lambda}]$$
(20)

Fortunately, this optimization simplifies into several separable problems: (1) $\{\alpha, \beta\}$, (2) σ , (3) γ , and (4) λ . Because solving for α and β jointly is non-concave, we solve for each separately. First consider α only:

$$\widehat{\boldsymbol{\alpha}} = \underset{\boldsymbol{\alpha}}{\operatorname{argmax}} \prod_{t,x=1}^{T,N_p} P_{\boldsymbol{\theta}}[F_{t,x}|C_t] = \underset{\boldsymbol{\alpha}}{\operatorname{argmax}} \prod_{t,x=1}^{T,N_p} \mathcal{N}(F_{x,t}; \alpha_x(C_t + \beta), \sigma^2)$$
(21a)

$$= \underset{\boldsymbol{\alpha}}{\operatorname{argmax}} \sum_{t=1}^{T, N_p} \log \mathcal{N}(F_{x,t}; \alpha_x(C_t + \beta), \sigma^2)$$
(21b)

$$= \underset{\alpha}{\operatorname{argmax}} - \frac{N_p T}{2} \log(2\pi\sigma^2) - \frac{1}{2\sigma^2} \sum_{t,x=1}^{T,N} (F_{t,x} - \alpha_x (C_t + b))^2$$
 (21c)

$$= \underset{\alpha}{\operatorname{argmin}} \sum_{t, x=1}^{T, N_p} (F_{t,x} - \alpha_x (C_t + \beta))^2. \tag{21d}$$

Therefore, we can solve for each of the N_p $\hat{\alpha}_x$'s separately and efficiently using Matlab's mldivide,

$$\widehat{\alpha}_x = (C + \beta \mathbf{1}) \backslash \mathbf{F}_x, \tag{22}$$

where $\boldsymbol{F}_x = [F_{1,x}, \dots, F_{T,x}]^\mathsf{T}$. Given $\widehat{\boldsymbol{\alpha}}$, we can estimate β :

$$\widehat{\beta} = \underset{\beta>0}{\operatorname{argmax}} \sum_{t,x=1}^{T,N} (F_{t,x} - \widehat{\alpha}_x (C_t + \beta))^2 = \underset{\beta>0}{\operatorname{argmax}} \sum_{t,x=1}^{T,N} (F_{t,x} - \widehat{\alpha}_x C_t + \beta \widehat{\alpha}_x)^2$$
(23)

which can be solved efficiently again using Matlab's mldivide: $\widetilde{\beta} = \widehat{\alpha}_x \setminus \left(\sum_{t=1}^T F_{t,x} - \widehat{\alpha}_x C_t\right)$. If $\widetilde{\beta} < 0$, we simply let $\widehat{\beta} = 0$, else, $\widehat{\beta} = \widetilde{\beta}$.

²The approximation in (19) may be considered a first-order Laplace approximation

Given $\widehat{\alpha}$ and $\widehat{\beta}$, we can now estimate σ using the residuals, i.e.,

$$\widehat{\sigma}^2 = \frac{1}{TN_p} \left\| \vec{F} - \widehat{\alpha} (C^{\mathsf{T}} + \beta \mathbf{1}) \right\|^2$$
(24)

Alternately, we could simply find a segment of time in which it is clear that no spikes occurred, $\vec{F}_{s:t}$, and then let $\hat{\sigma} = \text{Var}(\vec{F}_{s:t})$, which is independent of our inference algorithm.

Although estimating γ is rather straightforward, previous work [11] and unpublished results suggest that errors in estimating γ do not significantly impact inference quality, and that deviations in γ are relatively small across a population of neurons, so it can typically be "eyeballed".

Estimating λ is also totally straightforward:

$$\widehat{\lambda} = \frac{1}{T\Delta}\widehat{n}'\mathbf{1} \tag{25}$$

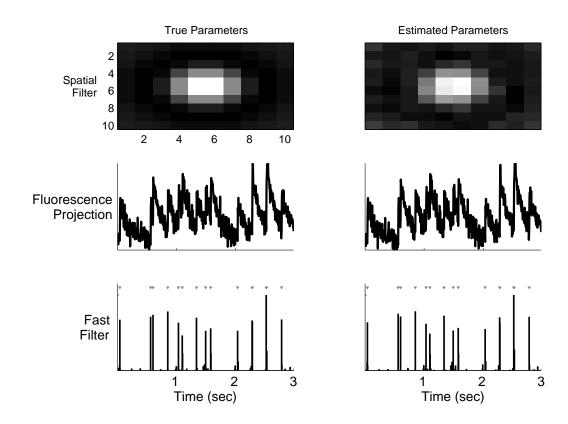

Figure 7: A simulation demonstrating that given only the fluorescence movie, the parameters may be estimated, and the spike train inferred (c.f. Supplementary Movie 2). Top left panel: true spatial filter. Middle left panel: projection of movie onto true spatial filter. Bottom left panel: inferred spike train using true parameters. Right panels: same as left except estimating parameters. α initialized with the first singular value of F. β initialized with O. λ and σ were initialized at double their true value. τ was assumed known. Parameters same as above.

3.4 in vitro data

3.5 Overlapping spatial filters

Model

$$\boldsymbol{F}_{t} = \sum_{i=1}^{N_{c}} \boldsymbol{\alpha}_{i} (C_{i,t} + \beta_{i}) + \boldsymbol{\varepsilon}_{t}, \qquad \boldsymbol{\varepsilon}_{t} \sim \mathcal{N}(\boldsymbol{0}, \sigma^{2} \boldsymbol{I})$$
 (26)

$$C_{i,t} = \gamma_i C_{i,t-1} + n_{i,t}, \qquad n_{i,t} \sim \text{Poisson}(n_{i,t}; \lambda_i \Delta)$$
 (27)

implicit assumption that $n_i \perp n_j$, $\forall i \neq j$

Inference let $\boldsymbol{n}=(n_{1,1},n_{2,1},\ldots,n_{N_c,1},n_{1,2},\ldots,n_{N_c,T})^\mathsf{T}$. similar def of \boldsymbol{C} .

$$\mathbf{M} = \begin{bmatrix} 1 & 1 & 0 & 0 & \cdots & \cdots \\ 1 & -\gamma_1 & 1 & -\gamma_2 & \dots & 1 & -\gamma_{N_c} & 0 & \cdots \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \dots & 1 & -\gamma_{N_c-1} & 1 & -\gamma_{N_c} \end{bmatrix}$$
(28)

inference as before, but replacing the scalar β with $\beta = (\beta_1, \dots, \beta_{N_c})^\mathsf{T}$, and making minor adjustments to deal with dimensionality issues.

Learning estimating $\boldsymbol{\alpha} = (\boldsymbol{\alpha}_1, \dots, \boldsymbol{\alpha}_{N_c})^\mathsf{T}$ is similar. now, we compute $\widehat{\boldsymbol{\alpha}}_x = (\widehat{\alpha}_{1,x}, \dots, \widehat{\alpha}_{N_c,x})^\mathsf{T}$ using

$$\widehat{\alpha}_x = (C + \widetilde{\beta}) \backslash F_x, \tag{29}$$

where $\widetilde{\beta}$ is β reparameterized to be the same size as C.

estimating β proceeds as before, but since it is a vector, we use Matlab's quadprog, imposing the constraint that $\beta_i > 0 \,\forall i$.

A Wiener Filter

Sections 2.3 outline one approach to solving Eq. (3), by approximating the Poisson distribution with an exponential distribution, and imposing a non-negative constraint on the inferred \hat{n} . Perhaps a more straightforward approach would be to approximate the Poisson distribution with a Gaussian distribution. In fact, as rate increases above about 10 spikes/sec, a Poisson distribution with rate $\lambda\Delta$ is well approximated by a Gaussian with mean and variance $\lambda\Delta$. Given such an approximation, instead of Eq. (6), we would obtain:

$$\widehat{\boldsymbol{n}}_w \approx \underset{n_t \in \mathbb{R}, \forall t}{\operatorname{argmin}} \sum_{t=1}^T \left(\frac{1}{2\sigma^2} (F_t - C_t)^2 + \frac{1}{2\lambda \Delta} (n_t - \lambda \Delta)^2 \right)$$
 (35)

As above, we can rewrite Eq. (35) in matrix notation in terms of C:

$$\widehat{\boldsymbol{C}}_{w} = \operatorname*{argmin}_{C_{t} \in \mathbb{R}, \forall t} \frac{1}{2\sigma^{2}} \left\| \boldsymbol{F} - \boldsymbol{C} \right\|^{2} + \frac{1}{2\lambda\Delta} \left\| \boldsymbol{M}\boldsymbol{C} - \lambda\Delta\boldsymbol{1} \right\|^{2}$$
(36)

which is quadratic in C, and may therefore be solved analytically using quadratic programming, $\hat{C}_w = \hat{C}_0 + d_w$, where \hat{C}_0 is the initial guess and $d_w = H_w \backslash g_w$, where

$$\boldsymbol{g}_{w} = \frac{1}{\sigma^{2}} (\boldsymbol{C}_{0}' - \boldsymbol{F}) + \frac{1}{\lambda \Delta} ((\boldsymbol{M} \widehat{\boldsymbol{C}}_{0})' \boldsymbol{M} - \lambda \Delta \boldsymbol{M}' \boldsymbol{1})$$
(37)

$$\boldsymbol{H}_{w} = \frac{1}{\sigma^{2}} \boldsymbol{I} + \frac{1}{\lambda \Delta} \boldsymbol{M}' \boldsymbol{M} \tag{38}$$

Note that this solution is the optimal linear solution, under the assumption that spikes follow a Gaussian distribution, and if often referred to as the Wiener filter, regression with a smoothing prior, or ridge regression. To estimate the parameters for the Wiener filter, we take the same approach as above:

$$\widehat{\boldsymbol{\theta}}_{w} \approx \underset{\boldsymbol{\theta}_{w}}{\operatorname{argmax}} P[\boldsymbol{F}|\widehat{\boldsymbol{n}}_{w}, \boldsymbol{\theta}_{w}) P[\widehat{\boldsymbol{n}}_{w}|\boldsymbol{\theta}_{w})$$
(39a)

$$= \underset{\boldsymbol{\theta}_{w}}{\operatorname{argmax}} - \frac{T}{2} \log(4\pi^{2}\sigma^{2}\lambda\Delta) - \frac{1}{2\sigma^{2}} \|\boldsymbol{Y}_{w} + \boldsymbol{\eta}_{w}\boldsymbol{X}_{w}\|^{2} - \frac{1}{2\lambda\Delta} \|\widehat{\boldsymbol{n}}_{w} - \lambda\Delta\boldsymbol{1}\|^{2}$$
(39b)

where Y_w , η_w , and X_w are defined as their subscriptless counterparts in Eq. (19).
